Topic 3

Welfare and Optimal Monetary policy

Mark Gertler
Spring 2019
Overview

Solve for and characterize optimal monetary policy rule

Use the utility of the representative agent as the welfare criteria

Consider discretion and the gains from commitment

Conclusions depend on scenario:

- No short run inflation/output tradeoff (baseline) versus tradeoff
- Efficient steady state (baseline) versus non-efficient steady state
- No liquidity trap versus liquidity trap.
Output/Inflation Tradeoffs

Consider baseline model with both productivity and demand shocks

Inflation given by

$$\pi_t = \omega mc_t + \beta E_t \pi_{t+1}$$

Assuming NO labor market frictions

$$mc_t = -\mu_t = \kappa (y_t - y^*_t) = \kappa \tilde{y}_t$$

$$\pi_t = \lambda \tilde{y}_t + E_t \pi_{t+1}$$

$$= E_t \sum_{i=0}^{\infty} \beta^i \lambda \tilde{y}_{t+i}$$

$$\lambda = \omega \kappa$$

If CB can commit to $\tilde{y}_{t+i} = 0$, no short run tradeoff. ("divine co-incidence"; Blanchard)
Labor Market Frictions

Adding labor market friction (simple 1st pass)

- Let $\mu^w_t$ be the log wage markup

\[
\begin{align*}
    w_t - p_t &= \mu^w_t + \varphi l_t + \gamma c_t
\end{align*}
\]

With $w_t - p_t$ sticky and $l_t, c_t$ procyclical $\Rightarrow \mu^w_t$ is countercyclical.

For now we take $\mu^w_t$ as exogenous. Possible to endogenize it by introducing wage rigiditiy (see Gali ch. 6)
wage markup

\[ w_t - p_t = \mu_t^w + \varphi l_t + \gamma c_t \]

price markup

\[ y_t - l_t = \mu_t^p + w_t - p_t \]

with \(-\mu_t^p = mc_t = (w_t - p_t) - (y_t - n_t)\)

combine equations:

\[ y_t - l_t = \mu_t^p + \mu_t^w + \varphi l_t + \gamma c_t \]

\[ = \mu_t + \varphi l_t + \gamma c_t \]

with \(\mu_t^p + \mu_t^w = \mu_t\)
Labor Market Frictions (con’t)

Using the same reasoning as in the baseline model of Topic 2:

\[ \mu_t = -\kappa \tilde{y}_t \]
\[ \mu^p_t + \mu^w_t = -\kappa \tilde{y}_t \]
\[ \mu^p_t = -\kappa \tilde{y}_t - \mu^w_t \]

given \( mc_t = -\mu^p_t \rightarrow \)

\[ mc_t = \kappa \tilde{y}_t + \mu^w_t \]

Note: \( y^*_t \) is solution for \( y_t \) given flexible prices and \( \mu^w_t = 0 \). (Note \( \mu^w_t \) is the log deviation of the wage markup from it’s steady state value.)
Labor Market Frictions (con’t)

\[
\pi_t = \omega mc_t + \beta E_t \pi_{t+1} \\
= \omega \kappa \tilde{y}_t + \omega \mu_t^w + E_t \pi_{t+1} \rightarrow \\
\pi_t = \lambda \tilde{y}_t + E_t \pi_{t+1} + u_t
\]

with \( \lambda = \omega \kappa \) and where the "cost push shock" is given by

\[
u_t = \omega \mu_t^w
\]

Iterating forward

\[
\pi_t = E_t \left\{ \sum_{i=0}^{\infty} \beta^i \left[ \lambda \tilde{y}_{t+i} + u_{t+i} \right] \right\}
\]

Hence \( \pi_t \) depends on both \( \tilde{y}_{t+i} \) and \( u_{t+i} \) ⇒ short run tradeoff.

Alternative way to motivate \( u_t \): fluctuations in desired markup \( \mu_t^P \) (Gali ch.5).
Model Conditional on Path of $r_t^n$

Given $\tilde{y}_t = y_t - y_t^*$

$$y_t - y_t^* = -\sigma[(r_t^n - \mathbb{E}t\pi_{t+1}) - r_{t+1}^*] + \mathbb{E}t\{y_{t+1} - y_{t+1}^*\}$$

$$\pi_t = \lambda(y_t - y_t^*) + \beta\mathbb{E}t\pi_{t+1} + u_t$$

$$y_t^* = \frac{1+\varphi}{1+\varphi+(\gamma-1)(1-\alpha)}a_t$$

$$r_{t+1}^* = \rho + \frac{1}{\sigma}a_t - a_t + \frac{1+\varphi}{1+\varphi+(\gamma-1)(1-\alpha)}(\mathbb{E}ta_{t+1} - a_t) + \frac{1}{\sigma}(b_t - \mathbb{E}tb_{t+1})$$

where $u_t, a_t$ and $b_t$ all follow exogenous stationary first order processes.

$$a_t = \rho_a a_{t-1} + \varepsilon^a_t$$

$$b_t = \rho_b b_{t-1} + \varepsilon^b_t$$

$$u_t = \rho_u u_{t-1} + \varepsilon^u_t$$
Undistorted Natural (Flex Price) Equilibrium

Deterministic steady state with production subsidy \( s \) per output unit.

\[
(1 - \alpha) \frac{Y_t^*}{L_t} (1 + s) = (1 + \mu^p) \frac{W_t^*}{P_t^*}
\]

\[
\frac{W_t^*}{P_t^*} = (1 + \mu^w) \frac{L_t^{*\varphi}}{C_t^{*-\gamma}}
\]

\[\rightarrow\]

\[
(1 - \alpha) \frac{Y_t^*}{L_t^*} (1 + s) = (1 + \mu^p) (1 + \mu^w) \frac{L_t^{*\varphi}}{C_t^{*-\gamma}}
\]

\[
(1 - \alpha) \frac{Y_t^*}{L_t^*} (1 + s) = (1 + \mu) \frac{L_t^{*\varphi}}{C_t^{*-\gamma}}
\]

Let \( s = \mu \rightarrow \) deterministic steady state is first best

\[
(1 - \alpha) \frac{Y_t^*}{L_t^*} = \frac{L_t^{*\varphi}}{C_t^{*-\gamma}}
\]

\[\rightarrow Y_t^o = Y_t^*, \text{ efficient level of output}\]
Policy Objective

- Household Preferences

\[ U_t = E_t \sum_{i=0}^{\infty} \beta^i \left[ \frac{1}{1 - \gamma} C_{t+i}^{1-\gamma} + \frac{a_m}{1 - \gamma_m} \left( \frac{M_{t+i}}{P_{t+i}} \right)^{1-\gamma_m} - \frac{1}{1 + \varphi} L_{t+i}^{1+\varphi} \right] \]

- At the cashless limit (limit as \( a_m \to 0 \))

\[ U_t = E_t \sum_{i=0}^{\infty} \beta^i \left[ \frac{1}{1 - \gamma} C_{t+i}^{1-\gamma} - \frac{1}{1 + \varphi} L_{t+i}^{1+\varphi} \right] \]
The policy objective (con’t)

- Suppose the natural eq. is undistorted (e.g. firms receive a production subsidy financed by lump sum taxes that offsets the steady state markup.)

- A quadratic approximation of the objective about the steady state combined with a first order approximation of the model (see Gali, ch.4) yields

\[
\frac{U_t - \bar{U}}{u_c \bar{C}} \propto -\frac{1}{2} E_t \left\{ \sum_{i=0}^{\infty} \beta^i \left[ \kappa (\bar{y}_{t+i})^2 + \frac{\epsilon}{\omega} \pi_{t+i}^2 \right] \right\} + t.i.p.
\]

\[
\propto -\frac{1}{2} E_t \left\{ \sum_{i=0}^{\infty} \beta^i \left[ \eta (\bar{y}_{t+i})^2 + \pi_{t+i}^2 \right] \right\} + t.i.p.
\]

where \( t.i.p \equiv \) terms independent of policy and \( \eta \) is given by

\[
\eta = \frac{\omega \kappa}{\epsilon} = \frac{\lambda}{\epsilon}
\]

- The inflation term is due to the loss of efficiency from the dispersion of relative prices.
The policy objective (con’t)

- Using a first order approximation of the model to construct the objective is valid only if linear terms are not present in the approximation. Otherwise a second order approximation is needed
  - A linear term will be present if the optimal equilibrium differs from the flexible price equilibrium
  - Within linear terms in the objective and a linear approximation of the model, errors in the linear approximation will be of the same magnitude as the second error terms in the objective
  - If the linear term in the objective is "small", a linear approximation of the model is reasonable (see Gali, ch.5)
The policy problem (with an undistorted natural eq.)

\[
\begin{align*}
\text{max} & \quad \{r^n_{t+i}, \bar{y}_{t+i}, \pi_{t+i}\}_{i=0}^{\infty} - \frac{1}{2} E_t \left\{ \sum_{i=0}^{\infty} \beta^i \left[ \eta \bar{y}_{t+i}^2 + \pi_{t+i}^2 \right] \right\} \\
\text{subject to} & \\
\pi_{t+i} &= \lambda \bar{y}_{t+i} + \beta E_{t+i} \pi_{t+i+1} + u_{t+i} \\
\bar{y}_{t+i} &= -\sigma (r^n_{t+i} - E_{t+i} \pi_{t+i+1} - r^*_t + \pi_{t+i+1}) + E_t \bar{y}_{t+i+1} \\
u_{t+i+1} &= \rho_u u_{t+i} + \varepsilon_{t+i}^u
\end{align*}
\]

with, \(0 \leq \rho_u < 1\) and we assume where \(\varepsilon_{t+i}^u\) is an i.i.d. random variable with zero mean.
The policy problem (con’t)

Given the recursive structure, the policy problem can be solved in two stages:

First, choose $\tilde{y}_t$ and $\pi_t$ to solve:

$$\max_{\{\tilde{y}_{t+i}, \pi_{t+i}\}} \sum_{i=0}^{\infty} \frac{1}{2} E_t \left\{ \sum_{i=0}^{\infty} \beta^i \left[ \eta \tilde{y}_{t+i}^2 + \pi_{t+i}^2 \right] \right\}$$

s.t.

$$\pi_{t+i} = \lambda \tilde{y}_{t+i} + \beta E_{t+i} \pi_{t+i+1} + u_{t+i}$$

and the exogenous process for $u_t$.

Second, given $\tilde{y}_t$ and $\pi_t$ find $r_t^n$ to solve:

$$\tilde{y}_{t+i} = -\sigma \left( r_{t+i}^n - E_{t+i} \pi_{t+i+1} - r_{t+i+1}^* \right) + E_{t+i} \tilde{y}_{t+i+1}$$
The policy problem (con’t)

- Policy problem in the tradition of the classic Tinbergen-Theil targets and instruments problem:

- The combination of a quadratic loss function and linear constraints yields a certainty equivalent decision rule for the path of the instrument.

- Important difference: Target variables depend not only on the current policy but also on expectations about future policy.

\[
\pi_t = E_t \sum_{i=0}^{\infty} \beta^i (\lambda \tilde{y}_{t+i} + u_{t+i}) \\
\tilde{y}_t = -\sigma E_t \sum_{i=0}^{\infty} (r^n_{t+i} - \pi_{t+i+1} - r^*_{t+i+1})
\]

- Raises issues of credibility and time consistency of policy.
Rules vs. Discretion

- *Discretion.* A policy maker (central bank) operating under discretion chooses the current interest rate by reoptimizing in every period, without committing to future choices.

- *Rules.* Under a rule, the central bank commits to a plan for the path of interest rates, that may be a function of future state realizations, and then it sticks to it forever. (Ramsey policy).

- The key distinction between discretion and rules is whether the policy maker can, or cannot, commit to future plans in a credible way.
Discretion

Two step process: 1. Central bank optimizes at $t$ given beliefs about future. 2. Given central bank decision rule, private sector forms beliefs (rational expectations).

In each period, the central bank chooses $\tilde{y}_t$ and $\pi_t$ to maximize

$$-\frac{1}{2}[\eta \tilde{y}_t^2 + \pi_t^2] + F_t$$

subject to

$$\pi_t = \lambda \tilde{y}_t + f_t$$

with

$$F_t = -\frac{1}{2}E_t[\sum_{i=1}^{\infty} \beta^i(\eta \tilde{y}_{t+i}^2 + \pi_{t+i}^2)]$$

$$f_t = \beta E_t \pi_{t+1} + u_t$$

where the central bank takes $f_t$ and $F_t$ and given
Discretion (con’t)

- The FONC yields the following feedback policy:

\[ \tilde{y}_t = -\frac{\lambda}{\eta} \pi_t \]  \hspace{1cm} (7)

- The targeting rule (7) implies that the central bank should pursue a “lean against the wind” policy: whenever inflation is above target, contract demand below capacity by raising the interest rate, and vice-versa when it is below target.

- How aggressively the central bank should reduce \( \tilde{y}_t \) depends positively on the gain in reduced inflation per unit of output loss, \( \lambda \), and inversely on the relative weight placed on output loss, \( \eta \).
Discretion (con’t)

- To solve for the equilibrium values of $\pi_t$ and $\tilde{y}_t$ under discretion, combine the targeting rule with the AS curve to get:

$$
\pi_t = -\frac{\lambda^2}{\eta} \pi_t + \beta E_t \pi_{t+1} + u_t = \frac{\eta \beta}{\eta + \lambda^2} E_t \pi_{t+1} + \frac{\eta}{\eta + \lambda^2} u_t
$$

(8)

Iterating forward:

$$
\pi_t = \frac{\eta}{\eta + \lambda^2} E_t \sum_{i=0}^{\infty} \left( \frac{\eta \beta}{\eta + \lambda^2} \right)^i u_{t+i}
$$

(9)

Since $E_t u_{t+i} = \rho^i u_t$, we finally have:

$$
\pi_t = \eta q u_t
$$

(10)

$$
\tilde{y}_t = -\lambda q u_t
$$

(11)

where $q = 1/[(\lambda^2 + \eta(1 - \beta \rho_u))]$. 
Discretion (con’t)

• We can now recompute the optimal feedback policy for the interest rate $r^*_t$ by substituting the desired value of $\tilde{y}_t$ and $\pi_t$ into the IS curve:

$$r^*_t = \phi_{\pi}E_t\pi_{t+1} + r_{t+1}^* \tag{12}$$

where

$$\phi_{\pi} = 1 + \frac{(1 - \rho_u)\lambda}{\rho_u \sigma \eta} > 1$$

• The central bank adjusts the interest rate more than one-to-one with respect to expected inflation $E_t\pi_{t+1}$ (since $\phi_{\pi} > 1$). The intuition is as follows: if inflation is above target, the optimal policy requires raising real rates $(r^*_t - E_t\pi_{t+1})$ to contract demand.
The classic inflationary bias problem

Under the assumption that the flexible price equilibrium is Pareto optimal, the policy maker has no reason to target a level of output $y_t$ higher than the natural equilibrium $y_t^*$. If we relax this assumption, by eliminating the labor subsidy, we have a discrepancy between the natural level of output and the Pareto optimal level:

$$y^o_t = y_t^* + k$$

where, given $\mu = -\kappa(y^o_t - y_t^*)$, $k > 0$ is given by

$$k = y^o_t - y_t^* = \frac{1}{\kappa} \mu > 0$$

But then

$$y_t - y^o_t = \bar{y}_t - k.$$
The classic inflationary bias problem (con’t)

Thus the bliss point for the output gap $\tilde{y}_t$ is positive.

In this instance, under discretion steady state inflation may be inefficiently high, as originally emphasized by Kydland and Prescott (1977) and Barro and Gordon (1983) and many others.

This scenario proposed to explain persistently high inflation during the 1970s.
Welfare function: Distorted Natural Eq.

- Following Gali, if the natural eq. distortion is not too "large", we may approximate the objective function as

$$\max_{\{x_{t+i}, \pi_{t+i}\}_{i=0}^{\infty}} -\frac{1}{2} E_t \left\{ \sum_{i=0}^{\infty} \beta^i \left[ \eta(\tilde{y}_{t+i})^2 - 2\eta k \tilde{y}_{t+i} + \pi_{t+i}^2 \right] \right\}$$

which is equivalent to maximizing

$$\max_{\{x_{t+i}, \pi_{t+i}\}_{i=0}^{\infty}} -\frac{1}{2} E_t \left\{ \sum_{i=0}^{\infty} \beta^i \left[ \eta(\tilde{y}_{t+i} - k)^2 + \pi_{t+i}^2 \right] \right\}$$

- subject to the Phillips curve constraint as:

$$\pi_{t+i} = \lambda \tilde{y}_{t+i} + \beta E_{t+i} \pi_{t+i+1} + u_{t+i}$$
Optimal Policy Under Discretion: Distorted Natural Eq.

- Under discretion, the problem becomes:

\[
\max_{x_t, \pi_t} \frac{1}{2}[\eta(\tilde{y}_t - k)^2 + \pi_t^2] + F_t
\]

subject to

\[
\pi_t = \lambda \tilde{y}_t + f_t
\]

where

\[
F_t = -\frac{1}{2}E_t[\sum_{i=1}^{\infty} \beta(\eta(\tilde{y}_{t+i} - k)^2 + \pi_{t+i}^2)]
\]

\[
f_t = \beta E_t \pi_{t+1} + u_t
\]
Optimal Policy Under Discretion: Distorted Natural Eq. (con’t)

- The FOC is then:

  \[ \tilde{y}_t - \kappa = -\frac{\lambda}{\eta} \pi_t \]  

  (14)

- Proceeding as before we obtain the equilibrium values for \( \pi_t \) and \( \tilde{y}_t \) under discretion:

  \[
  \pi_t = \eta qu_t + \frac{\eta \lambda}{\lambda^2 + \eta(1 - \beta)} \kappa \\
  \tilde{y}_t = -\lambda qu_t + \frac{(1 - \beta) \eta k}{\lambda^2 + \eta(1 - \beta)}
  \]

  (15) \hspace{1cm} (16)

- Thus, there is a positive inflationary bias (\( \pi_t > 0 \) as \( u_t \) goes to zero), but no difference in output with respect to the baseline case.
Optimal Policy Under Discretion: Distorted Steady State (con’t)

Since $\beta$ is close to unity, we can gain intuition from the case where $\beta \approx 1$

- In steady state with $\beta \approx 1$

  $$\pi = \lambda \tilde{y} + \pi$$
  $$\tilde{y} = 0$$

  → No long run inflation/output tradeoff

- Given targeting rule, optimal policy under discretion

  $$\pi_t = \eta q u_t + \frac{\eta}{\lambda}$$
  $$\tilde{y}_t = -\lambda q u_t$$
Optimal Policy Under Discretion: Distorted Steady State (con’t)

\[
\begin{align*}
\pi_t &= \eta qu_t + \frac{\eta}{\lambda} k \\
\tilde{y}_t &= -\lambda qu_t
\end{align*}
\]

→ Positive steady state inflationary bias
→ Cyclical behavior of \( \pi_t \) and \( \tilde{y}_t \) unchanged from case of undistorted steady state

• Interest rate policy that supports this bias:

\[
r_t^n = \phi_\pi (E_t \pi_{t+1} - \frac{\eta}{\lambda} k) + r_{t+1}^* + \frac{\eta}{\lambda} k
\]

CB effectively accepts inflation target \( \frac{\eta}{\lambda} k > 0 \)
Institutional Solutions to the Inflationary Bias Problem

- Rogoff (1985) suggests to appoint a “conservative” central banker, who assigns little if not zero weight to the output gap ($\eta \approx 0$), in order to reduce the inflationary bias (to zero at the limit).
  - However, there will be very inefficient responses to shocks (see equation (15)).

- Blinder (1997): Alternatively, the central bank can commit to treating $k = 0$ in the objective in order to achieve the equilibrium allocation in the baseline model under discretion.
  - But, $k$ is not observable.

- Inflation targeting. Commit to zero (or slightly positive) steady state inflation:
  - Support with Taylor rule that has desired inflation target $\pi^0 < \frac{\eta}{\lambda} k$

\begin{equation}
r_t^n = \phi_{\pi} (E_t \pi_{t+1} - \pi^0) + r_{t+1}^*
\end{equation}
Rules: the gains from commitment

- By committing to a policy rule, the central bank is able to influence private sector expectations.

- Solve for the optimum of the welfare function (1) subject to equations (2), (3) and (4), where the choice of $\tilde{y}_t$ and $\pi_t$ potentially depends on the entire history of shocks. (Ramsey).

- Form the Lagrangian (general case with $k > 0$):

$$L = -E_t\left\{ \sum_{i=0}^{\infty} \beta^i \left[ \frac{1}{2} (\eta(\tilde{y}_{t+i}-k)^2 + \pi_{t+i}^2) + \xi_{t+i} (\pi_{t+i} - \lambda \tilde{y}_{t+i} - \beta \pi_{t+i+1} - u_{t+i}) \right] \right\}$$

where $\xi_{t+i}$ is the Lagrange multiplier associated with constraint (2).

- Note choice of $\pi_t$ at $t$ constrained by $E_{t-1}\pi_t$, expectations of $\pi_t$ at $t - 1$
Rules: the gains from commitment (con’t)

- The FOCs are:

\[
\frac{\partial L}{\partial \tilde{y}_{t+i}} = \eta(\tilde{y}_{t+i} - k) - \lambda \xi_{t+i} = 0 \tag{18}
\]

\[
\frac{\partial L}{\partial \pi_{t+i}} = \pi_{t+i} + \xi_{t+i} - \xi_{t+i-1} = 0 \quad \forall \ i \geq 1 \tag{19}
\]

\[
\frac{\partial L}{\partial \pi_t} = \pi_t + \frac{1}{2} \xi_t = 0 \tag{20}
\]

- $\xi_{t+i-1}$ reflects the constraint from commitment on currently policy choice. In the first period ($i = 0$), the central bank is not constrained by past behavior.

- Here we are using the certainty equivalency property. Expectations disappear because the optimal policy is state contingent, given the shock realization.
Rules: the gains from commitment (con’t)

- We obtain the following optimality conditions:

\[
\begin{align*}
\xi_{t+i} &= \frac{\eta}{\lambda}(\tilde{y}_{t+i} - k) \\
\pi_{t+i} &= -\frac{\eta}{\lambda}(\tilde{y}_{t+i} - \tilde{y}_{t+i-1}) \quad \forall \ i \geq 1 \\
\tilde{y}_{t+i} - \tilde{y}_{t+i-1} &= -\frac{\lambda}{\eta} \pi_{t+i} \quad \forall \ i \geq 1 \\
\tilde{y}_t - k &= -\frac{\lambda}{\eta} \pi_t
\end{align*}
\]

- For \( i \geq 1 \), difference rule for output as opposed to level rule. More effective at managing beliefs then level rule.
  - Equivalent to price level target

\[
\tilde{y}_{t+i} = -\frac{\lambda}{\eta} p_{t+i} \quad \forall \ i \geq 1
\]
Rules: the gains from commitment (con’t)

- Equilibrium for $i \geq 1$ given by targeting rule and Phillips curve

$$
\tilde{y}_{t+i} = -\frac{\lambda}{\eta} \pi_{t+i} + \tilde{y}_{t+i-1} \\
\pi_{t+i} = \lambda \tilde{y}_{t+i} + \beta E_t(\pi_{t+1+i}) + u_{t+i}
$$

- Compared to discretion:
  * no inflationary bias: steady state with $\tilde{y}_{t+i}$ and $\pi_{t+i} = 0$
  * History dependence in output from targeting rule → smaller movements in $\tilde{y}_{t+i}$ and $\pi_{t+i}$ required in response to cost push shock.

- In first period the optimal policy is the same as under discretion. (not constrained by past.)
  - Woodford’timeless perspective - act as if $i \geq 1$.
  - (Makes commitment more credible).
Thus, combining (7) and (5) with (6) yields:

\[ i_t = r_t^e + \Psi_t \mu_t \]

(8)

where \( \Psi_t \equiv \frac{\beta_\psi + \sigma (1 - \rho_\psi)}{\kappa^2 + \vartheta (1 - \beta_\psi)} > 0 \).

Applying the arguments of chapter 3, it is easy to see that (8) cannot be viewed as a desirable interest rate rule, for it does not guarantee a unique equilibrium and, hence, the attainment of the desired outcome. In particular, if "rule" (8) is used to eliminate the nominal rate in (7), the resulting equilibrium dynamics are represented by the system

\[
\begin{bmatrix}
    x_t \\
    \pi_t
\end{bmatrix} =
A_O
\begin{bmatrix}
    E_t \{ x_{t+1} \} \\
    E_t \{ \pi_{t+1} \}
\end{bmatrix} + B_O \mu_t
\]

(9)

where

\[
A_O = \begin{bmatrix}
1 \\
\frac{1}{\sigma}
\end{bmatrix}; \quad B_O = \begin{bmatrix}
-\frac{\Psi_t}{\sigma} \\
-\frac{\Psi_t}{\kappa \beta + \frac{\vartheta}{\sigma}}
\end{bmatrix}
\]

As argued in chapter 4, matrix \( A_O \) has always one eigenvalue outside the unit circle, thus implying that (9) has a multiplicity of solutions, only one of which corresponds to the desired outcome given by (5) and (6).

In the context of the present model, one can always derive a rule that guarantees equilibrium uniqueness (independently of parameter values), by appending to the expression for the equilibrium nominal rate under the optimal discretionary policy (given by (8)), a term proportional to the deviation between inflation and the equilibrium value of the latter under that policy, with a coefficient of proportionality greater than one (in order to satisfy the Taylor principle). Formally,

\[ i_t = r_t^e + \Psi_t \mu_t + \phi_\pi \left( \pi_t - \frac{\vartheta}{\kappa^2 + \vartheta (1 - \beta_\psi)} \mu_t \right) \]

(10)

where \( \Psi_t \equiv \frac{\sigma (1 - \rho_\psi) - \vartheta (\phi_\pi - \rho_\pi)}{\kappa^2 + \vartheta (1 - \beta_\psi)} \) and for an arbitrary inflation coefficient satisfying \( \phi_\pi > 1 \).

In practice, an interest rate rule like (10) is not easy to implement, for the reasons spelled out in chapter 4: It requires knowledge of the model's parameters, and real-time observation of variations in the cost-push shock and the efficient interest rate. Those difficulties have
Liquidity Trap

• ZLB: $r^n_t \geq 0$ (recall $r^n_t = \log(1 + r^n_t)$)

• Suppose $r^*_t > 0$, $r^*_{t+i} < 0$ for $i = 0$ to $k - 1$, then $r^*_{t+i} > 0$ afterwards

• $\Rightarrow$ the ZLB is binding for $K$ periods:

$$\tilde{y}_t = -\sigma E_t \sum_{i=0}^{k-1} (-\pi_{t+i+1} - r^*_{t+i+1}) - \sigma E_t \sum_{i=k}^{\infty} (r^n_{t+i} - \pi_{t+i+1} - r^*_{t+i+1})$$

where $r^*_{t+i+1} < 0$ when the ZLB binds.
Optimal Policy in a Liquidity Trap

- ZLB constraint \( r_{t+i}^n \geq 0 \iff \)
  \[
  \tilde{y}_{t+i} \leq -\sigma ( -E_{t+i} \pi_{t+i+1} - r_{t+i+1}^* ) + E_{t+i} \tilde{y}_{t+i+1}
  \]

- When the ZLB is binding, the central bank simply sets \( r_t^n = 0 \)

- How \( \tilde{y}_t, \pi_t \) behave depends on policy expected once outside the liquidity trap

- For simplicity, set \( k, u_{t+i} = 0 \).

- \( \rightarrow \) Policy problem:
  \[
  L = -E_t \left\{ \sum_{i=0}^{\infty} \beta^i \left[ \frac{1}{2} (\eta (\tilde{y}_{t+i})^2 + \pi_{t+i}^2) + \xi_{t+i} (\pi_{t+i} - \lambda \tilde{y}_{t+i} - \beta \pi_{t+i+1}) + \Omega_{t+i} (\tilde{y}_{t+i} - ( -\sigma ( -E_{t+i} \pi_{t+i+1} - r_{t+i+1}^* ) + E_{t+i} \tilde{y}_{t+i+1} )) \right] \right\}
  \]
Optimal Policy in a Liquidity Trap

For $i = 0$ to $k - 1$, $r_{t+i}^n = 0 \rightarrow$

$$\tilde{y}_{t+j} = -\sigma E_t \sum_{i=j}^{k-1} (-\pi_{t+i+1} - r_{t+i+1}^*) + E_t \tilde{y}_{t+k}$$

$$\pi_{t+j} = E_t \sum_{i=j}^{k-1} \beta^{i-j} \lambda \tilde{y}_{t+j} + \beta^{k-j} E_t \pi_{t+k}$$

Key point: $\tilde{y}_{t+j}$ and $\pi_{t+j}$ depends on $E_t \tilde{y}_{t+k}$ and $E_t \pi_{t+k}$. The central bank has leverage over the latter two (since the liquidity trap is over at $t + k$.)

Note also that during the liquidity trap, $\tilde{y}_{t+j-1} < \tilde{y}_{t+j}$ and $\pi_{t+j-1} < \pi_{t+j}$
Optimal Policy in a Liquidity Trap (con’t)

Computing the optimal policy at $t + k$ (first period outside liquidity trap)

i. Note first that at $t + k - 1$, the ZLB is binding, which implies $\Omega_{t+k-1} > 0$.

\[(\Omega_{t+k-1} = \partial L_{t+k-1}/\partial r^*_t > 0)\]

ii. Solve for the optimal policy at $t + k$ given $\Omega_{t+k-1} > 0$

iii. Check whether the policy violates the ZLB at period $t + k$.

If it does not, implement the policy with $r^n_t$.

Since $r^n_{t+k} > 0$, $\Omega_{t+k} = 0 \rightarrow$ the economy escapes the liquidity trap.

The optimal policy at $t + k + 1$ reverts to the standard optimum.

iv. If the ZLB still binds at $t + k$, set $r^n_{t+k} = 0$, and re-optimize at $t + k + 1$

v. Keep going until $r^n_{t+k+j} > 0$ at the optimum.
Optimal Policy in a Liquidity Trap (con’t)

Optimal policy at $t + k$, first period outside the liquidity trap

First order conditions:

$$\frac{\partial L_{t+k}}{\partial \tilde{y}_{t+k}} = \eta \tilde{y}_{t+k} - \lambda \xi_{t+k} - \frac{1}{\beta}\Omega_{t+k-1} = 0$$

$$\frac{\partial L_{t+k}}{\partial \pi_{t+k}} = \pi_{t+k} + \xi_{t+k} - \xi_{t+k-1} - \frac{\sigma}{\beta}\Omega_{t+k-1}$$

Combining equations

$$\tilde{y}_{t+k} - \tilde{y}_{t+k-1} = -\frac{\lambda}{\eta}\pi_{t+k} + \frac{\sigma}{\beta}\Omega_{t+k-1} + \frac{1}{\beta\lambda}(\Omega_{t+k-1} - \Omega_{t+k-2})$$

- If the ZLB did not bind in the previous to periods (i.e., $\Omega_{t+k-1} = \Omega_{t+k-2} = 0$), the policy rule reverts to the standard targeting rule under commitment).
Optimal Policy in a Liquidity Trap (con’t)

\[
\tilde{y}_{t+k} - \tilde{y}_{t+k-1} = -\frac{\lambda}{\eta} \pi_{t+k} + \frac{\sigma}{\beta} \Omega_{t+k-1} + \frac{1}{\beta \lambda} (\Omega_{t+k-1} - \Omega_{t+k-2})
\]

- If the ZLB binds in the previous period \((\Omega_{t+k-1} > 0)\), \(\tilde{y}_{t+k}\) is increasing in \(\Omega_{t+k-1}\).
  - i.e., the tighter the ZLB constraint at \(t + k - 1\), the lower should \(r^n_t\) be to push \(\tilde{y}_{t+k}\) higher
  - If \(\Omega_{t+k-1}\) is sufficiently high, the ZLB constraint could bind at \(t + k\)
  - If so, re-optimize at \(t + k - 1\). Repeat until the ZLB is no longer binding.

- What ensures convergence back to a "normal" equilibrium?
  - \(\tilde{y}_{t+k}\) is decreasing in \(\Omega_{t+k-2}\), a factor working to offset the initial stimulus when first outside the liquidity trap at \(t + k\).

- Once the ZLB has not been binding for three periods, the central bank reverts to the optimal policy under commitment with a non-binding ZLB.
subject to the sequence of constraints

\[ \pi_t = \beta \pi_{t+1} + \kappa x_t \]

\[ x_t \leq x_{t+1} + \frac{1}{\sigma} (\pi_{t+1} + r_t^n) \]

where \( r_t^n = -\epsilon \) for \( t = 0, 1, \ldots, t_\epsilon \) and \( r_t^n = \rho \) for \( t = t_\epsilon + 1, t_\epsilon + 2, \ldots \).

The associated Lagrangian is now given by

\[ L = \sum_{t=0}^{\infty} \beta^t \left[ \frac{1}{2} (\pi_t^2 + \vartheta x_t^2) + \xi_{1,t}(\pi_t - \kappa x_t - \beta \pi_{t+1}) + \xi_{2,t}(x_t - x_{t+1} - \frac{1}{\sigma}(\pi_{t+1} + r_t^n)) \right] \]

with associated first order conditions

\[ \pi_t + \xi_{1,t} - \xi_{1,t-1} - \frac{1}{\beta \sigma} \xi_{2,t-1} = 0 \]  

\[ \vartheta x_t - \kappa \xi_{1,t} + \xi_{2,t} - \frac{1}{\beta} \xi_{2,t-1} = 0 \]  

and slackness conditions

\[ \xi_{2,t} \geq 0; i_t \geq 0; \xi_{2,i_t} = 0 \]

as well as initial conditions \( \xi_{1,1} = \xi_{2,1} = 0 \).

The solution is conjectured (and subsequently verified) to be of the following form. From period 0 to \( t_C \geq t_\epsilon \) the nominal rate remains at zero. It becomes positive in period \( t_C + 1 \) and remains positive from then onward.

The equilibrium dynamics for \( t = t_C + 2, t_C + 3, \ldots \) are described by the difference equations

\[ \pi_t + \xi_{1,t} - \xi_{1,t-1} = 0 \]  

\[ \vartheta x_t - \kappa \xi_{1,t} = 0 \]  

\[ \pi_t = \beta \pi_{t+1} + \kappa x_t \]

together with an initial condition for \( \xi_{1,t_C+1} \) (to be determined below).
